Abstract

Background: Although considered one of the most important prognostic factors for lung cancer patients, the health-related quality of life (HRQOL) of the newly diagnosed lung cancer population remains scarcely focused on in the literature. Therefore, we aimed to identify the determinants of HRQOL among newly diagnosed lung cancer patients in Taiwan.

Methods: Two hundred and fifty patients newly diagnosed with lung cancer were recruited from a medical center in northern Taiwan through convenience sampling. Four structured questionnaires, including the Taiwanese version of the MD Anderson symptom inventory (MDASI-T), the Taiwanese version of the Pittsburgh Sleep Quality Index (PSQI-T), the International Physical Activity Questionnaire-Short Form (IPAQ-SF), and the World Health Organization Quality of Life-BREF (WHOQOL-BREF), were used to collect data. Further, a multivariate stepwise linear regression was conducted to determine the independent risk factors for HRQOL. A *p* value of less than 0.05 was considered statistically significant.

Results: The patients (mean age was 61.04 years, 51.2% male, 94.0% non-small-cell lung cancer, 56.4% stage III–IV) had moderate levels of HRQOL among the physical, psychological, social, and environmental domains, as well as overall QOL. HRQOL was not correlated with married status, religion, and comorbidity. Gender, age, family income, smoking status, cancer stage, ECOG PS scores, PA, symptom burden (severity and interference), and PSQI global scores were correlated with HRQOL. Notably, symptom severity was the dominant negative predictor affecting the psychological and environmental domains of QOL ($\beta = -4.313$ and -3.500 , respectively), accounting for 23.2% and 14.6% of the variance, respectively. On the other hand, symptom interference was the dominant negative predictor affecting the physical and social domains of QOL, as well as overall QOL ($\beta = -3.592$, -1.984 , and -0.150 , respectively), accounting for 44.4%, 15.0%, and 24.1% of the variance, respectively.

Conclusion: Newly diagnosed lung cancer patients suffered symptom severity and interference that significantly impaired their HRQOL; particularly, symptom interference affected the physical domain of QOL. Healthcare professionals should pay more attention to cancer-related symptom severity, symptom interference, and HRQOL changes when caring for newly diagnosed lung cancer patients.

Keywords: Comorbidity; Prognosis; Quality of life; Sleep quality; Smoking

1. INTRODUCTION

Lung cancer (LC) remains the world's leading cause of cancer-related mortality. According to the Lung Cancer Statistics Report, there were 228 150 new cases of LC and 142 670

LC-related deaths in the United States in 2019.¹ In Taiwan, LC ranks the second highest incidence in all cancers, with 39.8 cases of newly diagnosed LC per 100 000 persons in 2018.² In addition to the high incidence rate, LC was also the most common cancer-related deaths in Taiwan, with a mortality rate of 40.8 per 100 000 persons in 2020.²

Patients diagnosed with LC experience various discomforting symptoms. Many of these symptoms begin before diagnosis and continue throughout the illness and its treatment, negatively affecting patients' health-related quality of life (HRQOL).³ HRQOL is generally accepted as a multidimensional concept that assesses how diseases and treatments affect a patient's sense of overall well-being. It includes domains related to physical, mental, emotional, social functioning, and supportive environments.^{4,5} In addition, HRQOL has been considered one of the most important prognostic factors for LC survivors.^{6–11}

The HRQOL of newly diagnosed LC patients was reported to be lower than that of other cancer patients.¹² In recent years, some studies indicated that multiple factors were associated with HRQOL among patients with LC.¹³ These factors include demographic factors (age, gender, educational level, and smoking status), disease factors (cancer stage, treatment, and performance status),^{14–16} symptom burden (SB; symptom severity and interference),^{17–20} psychological distress (depression and anxiety),^{21,22} physical activity,^{23,24} and sleep quality.^{25,26} Compared to the quantity of available literature on the HRQOL of patients diagnosed with other major cancers, few studies have explored the HRQOL and its related factors among newly diagnosed LC patients before treatment. Hence, this study aimed to examine the relationships between the SB, physical activity (PA), sleep quality (SQ), and HRQOL among newly diagnosed LC patients.

2. METHODS

2.1. Study participants

This study is a cross-sectional design using convenience sampling. A total of 250 newly diagnosed LC patients were included between June 2015 and May 2017 at a medical center in northern Taiwan. The inclusion criteria were (1) ≥ 20 years of age; (2) diagnosed with LC for the first time (International Classification Diseases, 10th revision code, ICD-10: C34.0); and (3) has alert consciousness, can communicate, and is willing to participate. Patients diagnosed with secondary LC were excluded. All participants provided informed consent before participating in the study and were assessed on their diagnoses before receiving therapy. Further, this study was approved by the Institutional Review Board (IRB) of Taipei Veterans General Hospital (IRB no. 2015-05-005AC).

2.2. Measures

Participants were asked to complete a structured questionnaire comprised of demographics and disease characteristics, SB, PA, SQ, and HRQOL. The demographic and disease data included age, gender, educational level, body mass index (BMI), family income, smoking status, comorbidity, and cancer type, stage, and treatment. The Eastern Cooperative Oncology Group performance status (ECOG PS) scale assessed patients' self-care function with 5 points score (0–4).¹⁶ The data were recorded in the medical chart by the patients' oncologists. ECOG PS was classified as either good (scores of 0–1) or poor (scores of 2–4) performance; a higher score indicates poorer functioning level.²⁷

SB was measured using the symptom severity and symptom interference subscales with the Taiwanese version of the MD Anderson symptom inventory (MDASI-T).²⁸ The symptom severity subscale covers the 13 cancer-related symptom items: pain, fatigue, sleep disturbance, distress, shortness of breath, difficulty remembering, drowsiness, dry mouth, sadness, poor appetite, nausea, vomiting, and numbness. The symptom interference subscale consists of 6 items that address the level of interference from symptoms, including general activity, walking, normal work, mood, relationships with others, and enjoyment of life.^{29,30} Each item is rated on an 11-point Likert scale from 0 (not present) to 10 (as bad as you can imagine). MDASI-T was validated among 556 patients with multiple cancer diagnoses in Taiwan, with a Cronbach's α of 0.89 and 0.94 for symptom severity and interference items, respectively.²⁸ Meanwhile, the Cronbach's α of this study was 0.87 and 0.91 for symptom severity and interference items, respectively. The content validity index (CVI) scores judged by 3 experts were 1.0.

SQ was measured by the Taiwanese version of the Pittsburgh Sleep Quality Index (PSQI-T).³¹ The instrument comprises 19 items with 7 component scores. The component scores yield

a PSQI global score (0–21); a higher PSQI global score indicates poorer sleep quality, and the global score >5 is used to differentiate poor from good sleepers.³² The PSQI-T was well validated among 205 patients with various cancer diagnoses in Taiwan, with a Cronbach's α of 0.79.³³ On the other hand, the Cronbach's α for the PSQI-T of this study was 0.80. The CVI scores judged by 3 experts were 1.0.

The PA level was determined by the Taiwan version of the International Physical Activity Questionnaire-Short Form (IPAQ-SF).³⁴ The tool has been validated as an efficient method for assessing PA among Taiwanese LC patients.^{35–37} IPAQ-SF assesses 3 types of activity, including walking, moderate, and vigorous intensity activities, at least 7 d/wk. The 3 types of activity were computed by their energy requirements (walking = 3.3 METs, moderate PA = 4.0 METs, and vigorous PA = 8.0 METs) to yield a total PA score in metabolic equivalent of task-minutes per week (MET-min/wk). Three PA groups proposed to classify participants: low PA (LPA; total PA <600 MET-min/wk), moderate PA (MPA) (total PA ≥ 600 MET-min/wk), and high PA (HPA) (total PA ≥ 3000 MET-min/wk).³⁸

The HRQOL in this study was measured using the Taiwan version of the World Health Organization Quality of Life-BREF (WHOQOL-BREF) questionnaire. Among the 28 items, the first 2 general facet items evaluated the overall QOL (G1) and general health status (G2) based on a 1–5 scale, with higher scores indicating better G1 and G2. In addition to the 2 general items, the other 26 items were distributed into 4 domains: physical, psychological, social, and environmental. Two scorings (4–20 and 0–100; a higher score indicates better QOL) can be transformed into each domain score; the 0–100 scoring was used in this study. The Cronbach's α ranged from 0.70 to 0.77 for the 4 domains,³⁹ and the content validity coefficients were between 0.53 and 0.78 for item-domain correlations and 0.51 and 0.64 for inter-domain correlations.^{39,40} Lin et al⁴¹ showed that the WHOQOL-BREF has good construct validity, allowing clinicians to evaluate how LC survivors assess their sense of well-being. The analysis of the newly diagnosed LC patients in this study reported that Cronbach's α was 0.87, 0.81, 0.74, and 0.83 in the physical, psychological, social, and environmental domains, respectively.

The validity of IPAQ-SF and WHOQOL-BREF was not assessed in this study because the copyright holders did not allow any change to the instrument. Nevertheless, all questionnaires were approved for use in this study.

2.3. Data analysis

The SPSS v24.0 (IBM Co., Armonk, NY) software was used for the statistical analysis in this study. Categorical and continuous variables were demonstrated by numbers with percentages and means with standard deviation, respectively. A univariate analysis was performed for each QOL domain, with G1 and G2 scores as the dependent variables and demographics, disease characteristics, SB (severity and interference composite score), groups of PA, and the PSQI global score as independent variables. Further, a multivariate stepwise linear regression analysis was used to assess the association among the significant factors in the univariate analysis and each dependent variable under adjustment for potentially confounding variables. The variance inflation factor (VIF) was used to detect multicollinearity in regression analysis, in which a p value of less than 0.05 was considered statistically significant.

3. RESULTS

A total of 250 patients (aged 35–88 years, 51.2% male, 94.0% non-small-cell LC, 56.4% stage IIIB–IV) were included in this

study. The demographics and disease characteristics are listed in Table 1.

The top three prevalent symptoms among newly diagnosed LC patients were disturbed sleep, fatigue, and dry months; the mean severity scores of the three symptoms ranged from 2.14 to 3.24. In addition, the top three prevalent interferences from symptoms were mood, enjoyment of life, and working; the mean scores of the three interferences ranged from 2.63 to 2.72. The details of the prevalence are presented in Figure 1. The mean symptom severity and interference scores were 1.72 ± 1.47 and 2.26 ± 2.43 , respectively. Approximately half of the patients were classified as the LPA group. The mean PSQI global score (7.85

± 4.67 ; 62.4%) of the newly diagnosed lung cancer patients showed poorer sleep quality (PSQI global score >5). On average, the newly diagnosed LC patients reported moderate levels of HRQOL. Among the four QOL domains of the newly diagnosed LC patients, the social domain scored the highest, with a mean score of 68.26 ± 15.14 , while the psychological domain scored the lowest, with a mean score of 59.14 ± 16.19 . The mean G1 and G2 scores were 3.10 ± 0.93 and 2.58 ± 0.98 , respectively. The distributions of SB scores, physical activity groups, PSQI global scores, and HRQOL scores are presented in Table 2.

The detailed univariate analysis is presented in Table 3. Notably, there was a positive correlation between age and the environmental QOL score ($\beta = 0.224$, $p = 0.01$), and women had significantly better QOL than men in the social domain ($p < 0.001$). Significant differences between educational levels ($p < 0.05$) were reported in physical, psychological, and environmental QOL and G1 and G2. The physical QOL of underweight patients (BMI < 18.5 kg/m²) was worse than others ($p < 0.05$). Low family income and advanced-stage cancer were significantly associated with a lower QOL score in the four domains ($p < 0.05$). Smoking status was significantly associated with physical, social, and environmental QOL and G1 and G2. Higher ECOG PS scores were significantly correlated with lower QOL in the physical, psychological, and environmental domains ($p < 0.01$). However, married status, religion, and comorbidity did not significantly correlate with any QOL domains ($p > 0.05$). The scores of symptom burden (including symptom severity and interference) and global PSQI had significantly negative correlations with the two general facet items (G1 and G2) and the four QOL domains (all $p < 0.001$). The scores of G1, G2, and the four QOL domains in both HPA and MPA groups were significantly higher than in the LPA group ($p < 0.01$).

A multivariate stepwise linear regression was used to determine the predictors of the physical, psychological, social, and environmental domains of QOL, as well as overall QOL. The VIF for all variables was below 5, indicating the absence of a multicollinearity problem. Further, this study found that gender, age, family income, smoking status, cancer stage, ECOG PS scores, PA, symptom severity, symptom interference, and PSQI global scores predicted the HRQOL of newly diagnosed LC patients. Different combinations of the predictors accounted for 57.5%, 26.9%, 21.7%, 22.4%, and 30.7% of the physical, psychological, social, environmental, and overall QOL, respectively. The PSQI global score was a significant predictor in the overall QOL and all QOL domains, except for the environmental domain; however, it explained less variance in any regression model. SB (including symptom severity and interference) was the most robust factor for predicting HRQOL among newly diagnosed LC patients. Symptom severity was the dominant predictor affecting the psychological and environmental QOL, accounting for 23.2% and 14.6% of the variance, respectively. Symptom interference was the dominant predictor affecting the physical, social, and overall QOL, accounting for 44.4%, 15.0%, and 24.1% of the variance, respectively (Table 4).

4. DISCUSSION

Assessments of baseline HRQOL are seldom performed in newly diagnosed LC patients in Taiwan, despite being one of the most important prognostic factors of survival for cancer patients, particularly LC. The clinical significance of this cross-sectional study describes the HRQOL and identifies its related factors in patients with newly diagnosed LC; however, it does not propel cancer treatments in Taiwan.

The participants in this study have moderate levels of QOL in the 4 domains of WHOQOL-BREF (the mean scores ranged from 59.40 to 68.26). This finding is consistent with the findings

of a previous study.⁴² However, the result differs from that of Cai et al,⁴³ which showed that 108 newly diagnosed LC patients had poor QOL in all 4 QOL domains. The possible reason for the finding in the said study might be related to patients' disease characteristics with a higher proportion of stage IIIB–IV (85%), unlike the proportion in this study (56%). In the present study, the worse PS was related to the deterioration of physical and psychological QOL. Similar results had been observed in a previous study,⁴⁴ probably because a worse PS likely results in functional difficulties and emotional distress, affecting QOL in advance.

The results of this study showed that newly diagnosed LC patients with moderate or high PA had better HRQOL in any domain compared with those with LPA. The higher PA

demonstrated in the previous studies was positively correlated with the HRQOL of LC survivors or patients with advanced-stage LC.^{23,45,46} However, another study reported that a moderate-to-vigorous intensity PA was not associated with HRQOL among LC survivors,²⁴ possibly due to patients' differing LC stages. Therefore, further studies are recommended to explore this issue among patients in terms of disease trajectories. Furthermore, this study revealed that most newly diagnosed LC patients showed poorer sleep quality, which was significantly correlated with HRQOL. The result was similar to a previous study, where many patients were not newly diagnosed with LC.²⁶ Such a phenomenon may be due to the fact that patients are vulnerable to poor sleep, regardless of their cancer stages—an aspect worth exploring in the future.

In terms of SB, the study revealed that symptom severity and symptom interference were significantly negatively correlated with overall QOL among newly diagnosed LC patients. The findings were consistent with the other studies that employed LC patients and survivors with other stages.^{17–19,25,47} In addition, this study used the Taiwan version of WHOQOL-BREF and MDASI to explore the association between HRQOL and SB among newly diagnosed LC patients. The findings may be used as references for accessible clinical care to improve the quality of life of all LC patients. It can also be employed to validate the outcomes for future studies.

To our knowledge, this study is the first survey to focus on and investigate the SB, PA, SQ, and HRQOL of newly diagnosed LC patients. However, some limitations need to be pointed out. First, it is difficult to understand the cause-and-effect relationship and the trajectory change of HRQOL over time in a cross-sectional study. Second, the population in this study was determined through convenience sampling and is limited to a medical center, potentially influencing the representativeness of newly diagnosed LC patients.

In conclusion, this study shows that newly diagnosed LC patients in Taiwan have moderate levels of HRQOL, and its related factors include gender, age, family income, smoking status, cancer stage, ECOG PS scores, PA, SB (symptom severity, symptom interference), and PSQI global scores. Noteworthy,

the symptom severity is the strongest negative predictor for the psychological and environmental QOL domains, and symptom interference is the strongest negative predictor for the physical and social QOL domains, as well as overall QOL. These findings imply that healthcare professionals should pay more attention to SB to optimize HRQOL when caring for patients diagnosed with LC for the first time. Furthermore, they can be used as a reference in future studies related to the relationships between the earlier assessment of the HRQOL and the related factors among newly diagnosed LC patients and the outcomes of the disease progression.
